## Summary

This report presents the development, characterization, and arc-jet testing of Phenolic Impregnated Carbon Ablators (PICA), a member of the Lightweight Ceramic Ablators (LCAs) family developed at Ames Research Center. LCAs consist of a low density fibrous substrate impregnated with an organic resin. PICA uses a pre-formed fibrous carbon tile manufactured by Fiber Materials, Inc. as the substrate, and phenolic as the organic infiltrant. Innovative infiltration techniques were developed to produce PICA with densities ranging from 14 to 65 lbm/ft<sup>3</sup>; however, only the low density PICA samples were used to evaluate the material's thermal performance. Arc-jet testing of low density PICA showed that these materials can withstand very high heating rates and surface pressures and are more mass efficient than most traditional ablative materials (ref. 1). The manufacturing process of PICA has since been refined to give repeatable performance among batches, and its thermal performance is being further evaluated. Surface densification was also recently developed to improve the ablation characteristics in high heating and surface pressure environments.

The thermal performance and ablation characteristics of PICA were evaluated in an oxidizing environment in the Ames Research Center 60 megawatt (MW) Interaction Heating Facility (IHF). Samples of PICA with and without surface densification, the carbon preform, and Avcoat-5026 (the Apollo heat shield), were tested at cold wall heat fluxes of 375 to 2960 Btu/ft<sup>2</sup>-s and surface pressures from 0.1 to 0.43 atm. Resulting heat loads during these tests ranged from 5500 to 29,600 Btu/ft<sup>2</sup>. Surface and in-depth temperatures were measured using optical pyrometers and thermocouples, respectively. Mass loss was measured for each sample and surface recession was measured using a height gage. Various material

characterization tests were also performed on virgin (pre-test) and charred (post-test) PICA samples.

## Introduction

During the past two decades, there has been very little effort toward developing new lightweight ablative heat shields for planetary entry vehicles. Traditional ablators, such as SLA-561V and Avcoat-5026H/C, were developed several decades ago to support the Viking and Apollo missions. In recent years, the national priority has been re-focused on the exploration of other planets, and the need for advanced ablative materials became apparent. These planetary missions would require a heat shield that can withstand very high heating rates and shear loads, while providing the necessary thermal protection for the interior of the vehicle. In addition, a low density material is desirable to minimize the weight of the heat shield, allowing the weight of the scientific payload to be maximized.

A family of materials called Lightweight Ceramic Ablators (LCAs) were developed at Ames Research Center to fulfill the needs of these future planetary missions. LCAs are low density materials that utilize precursor technologies to simplify the manufacturing process and minimize manufacturing costs. Arc-jet tests show that these materials can withstand very high heating rates and shear loads with a savings in weight up to 50% when compared to traditional ablators (ref. 1).

The manufacturing processes of LCAs have been significantly improved since their initial conception, and several optimization approaches were investigated. The objective of this arc-jet test series was to investigate the thermal performance and ablation characteristics of various compositions of PICA at a wide range of heat fluxes, surface pressures, and heat loads.

## Materials

LCAs, in general, consist of a fibrous ceramic substrate impregnated with an organic resin. PICA utilizes a fibrous carbon Fiberform<sup>®</sup> insulation manufactured by

<sup>\*</sup>H.C. Chem, 15221 Skyview Dr., San Jose, CA 95133.

<sup>†</sup>Thermosciences Institute, Moffett Field, CA 94035.

<sup>‡</sup>Foothill-De Anza College, 21250 Stevens Creek Blvd., Cupertino, CA 95014.

Fiber Materials, Inc.<sup>1</sup> and phenolic resin as the infiltrant. Fiberform is a commercial insulation material which has been optimized for vacuum or inert furnaces. Fiberform is produced by chopping carbon fibers of 14–16 µm diameter and 1600 µm length in a water slurry. A water soluble phenolic resin is added to the slurry, mixed and vacuum cast. The green billet is then dried, resin cured, and carbonized to 1440°F, and then heat treated at 3240°F. Due to its high porosity, the Fiberform, in general, has fairly low thermal conductivity compared to the high density solid graphite and its counter part, the carbon foam. It is also the basis in the selection of high temperature substrates for LCA materials.

The SC1008 phenolic infiltrant used in the production of PICA is a phenol-formaldehyde resin formed through polycondensation reactions between phenol and formaldehyde in the presence of suitable catalysts by a one- or two-stage process (ref. 2). Figure 1 shows the polymerization process of the phenolic resins using a one-stage process (a); the reaction is interrupted at A- or B-stage resins to prevent crosslinking. For the two-stage process (b), the reaction can be carried out nearly to completion without three-dimensional crosslinking. Final crosslinking is accomplished after application of A- or B-stage resins or molding powder to produce a thermoset material. Figure 2 shows the molecular structure of the cured phenolic resins.

Initial densities of the carbon Fiberform used in this test series ranged from 8.5 to 11 lbm/ft<sup>3</sup>. Innovative impregnation techniques<sup>2</sup> were used to produce standard PICA test samples with final densities ranging from 14 to 17 lbm/ft<sup>3</sup>.

Surface densification was performed on several test samples to investigate the difference in ablation characteristics and thermal performance when compared with standard PICA samples. Surface densification increased the final densities of the PICA materials, ranging from 18 to 23 lbm/ft<sup>3</sup>. Table 1 summarizes the composition of each densified test sample, denoted with a “D” following the sample identification number. Several samples of the carbon substrate (10 to 11 lbm/ft<sup>3</sup>) and one sample of the traditional ablator Avcoat-5026 (32 lbm/ft<sup>3</sup>) were tested to compare with the PICA samples.

## Material Testing and Analysis

It is necessary to obtain the thermophysical and thermochemical properties of the material to evaluate the ablation characteristics and thermal performance. Various tests were performed to characterize and fully understand the performance of the various compositions of PICA.

### 1. Thermal Properties Measurements

Initial thermal property measurements were taken to characterize PICA material. Thermal conductivity measurements were made on the Fiberform and PICA materials, and thermogravimetric analysis was performed on the phenolic resins and PICA material in an inert and oxidizing environment.

#### a. Thermal conductivity

Fiberform is commercially used as insulation for vacuum and inert furnaces, thus, its thermal conductivity is fairly low. The material exhibits an anisotropy in its thermal and mechanical performance. The thermal conductivity in the strong direction, i.e., direction of fibers, is about 2.4 times higher than that of the weak direction, through the thickness. In most cases, the ablating surface on a typical heat shield would be perpendicular to the weak direction. The thermal conductivity of this material increases with increasing temperature and can be expressed as an Arrhenius function (ref. 3),

$$K = Ae^{BT}$$

where

K the thermal conductivity, Btu-in/ft<sup>2</sup>-hr-°F

A a material dependent constant, which is in essence, the thermal conductivity at 32°F

B a material dependent constant which is a measure of how rapidly the thermal conductivity increases with temperature

T the mean temperature, °F

Figure 3 shows the typical behavior of the thermal conductivity of the Fiberform as a function of mean temperature. The influence of density on the conductivity coefficients A and B are shown in figures 4 and 5, respectively. As expected, the coefficient A increases with density, but coefficient B is inversely proportional to density. The primary reason for this inverse trend is the influence of internal radiative heat transfer on the thermal conductivity in a fibrous material. As the density increases, the porosity decreases, and the internal structure has more integrity, which results in a reduction of the radiation contribution to the overall heat transfer.

<sup>1</sup>Fiber Materials, Inc., “Some Comments on the Thermal Conductivity of Carbon Fiberform Insulation,” FMI internal report.

<sup>2</sup>Patent pending.

The importance of internal radiative heat transfer on the overall thermal conductivity at high temperatures is demonstrated in figure 6, which shows the combined influence of density on conductivity for Fiberform as a function of temperature (see footnote 1). The low density materials (9 and 10.6 lbm/ft<sup>3</sup>) have lower thermal conductivity at temperatures up to 2000°F, but cross over to a much higher conductivity above 2000°F. Fiberform with a density of 14.4 lbm/ft<sup>3</sup> has a slightly higher thermal conductivity at temperatures below 2000°F and significantly lower conductivities at temperatures in excess of 2700°F.

Thermal conductivities of PICA materials were measured at various pressures using the ASTM D 27766-86 and ASTM E1461-92. PICA with 30% phenolic resin in the 10 lbm/ft<sup>3</sup> density Fiberform was selected for this measurement. Thermal conductivity was calculated at each temperature from the measured thermal diffusivity,  $\alpha$ , density,  $\rho$ , and heat capacity,  $C_p$ , by using the following expression,  $K = \alpha \rho C_p$ .

Figures 7, 8, and 9 show the heat capacity, thermal diffusivity, and thermal conductivity, respectively, of PICA-15 (10 lbm/ft<sup>3</sup> Fiberform and 4.5–5 lbm/ft<sup>3</sup> phenolic) at pressures of 0.05, 0.01, 0.001 atm. The results show that pressure has a small effect on the conductivity of PICA, and at temperatures below 2000°F, PICA has a thermal conductivity of about 2.56 Btu-in/hr-ft<sup>2</sup>-°F. As the temperature increases to 5000°F, the thermal conductivity reaches as high as 11.91 Btu-in/hr-ft<sup>2</sup>-°F. It is interesting to note that the thermal conductivity of PICA is a factor of two lower than that of the original Fiberform (10.6 lbm/ft<sup>3</sup> on fig. 6) at higher temperatures, and is almost equal to that of the Fiberform of the same density (14.4 lbm/ft<sup>3</sup> on fig. 6). The presence of phenolic reduces the pore size within the matrix and thus reduces the radiation term in the heat transfer balance equation. This result is consistent with internal radiative heat transfer theory.

#### *b. Thermogravimetric Analysis (TGA)*

Thermogravimetric analysis measures the mass change of a decomposing material as a function of temperature at a constant heating rate. The decomposition temperature and the char yield of the polymer can be determined from this analysis. TGA analysis on post-test samples provides insight into the amount of pyrolysis that occurred through the thickness of the material.

Figure 10 shows the char yields obtained from TGA for the phenolic resin tested in argon. Typically, phenolic has about 50–60% char yield depending on the relative degree of cross-linking of the molecules. As shown in figure 10, the phenolic begins to pyrolyze at about 300°F,

and the pyrolysis is complete at 1400°F, yielding a char residue of 62.563%. Figures 11(a) and (b) show the decomposition process for PICA in argon and in air at a heating rate of 20°/min. In both air and argon, the weight loss begins at approximately 700°F and is completed at about 1300°F for the argon case, and 1500°F for the air case. In argon, the weight loss in PICA exhibits a smooth transition and yields a char residue of 78.472%. In air, the weight loss of PICA consists of two stages. The first stage, from 500°F to 1100°F, is weight loss due to gas pyrolysis of phenolic and is consistent with that observed in argon. The second stage is due to the oxidation of the carbonaceous char which is complete at 1500°F.

## 2. Mechanical Properties Measurements

The tensile strength of PICA-15 was measured in the transverse and in-plane directions, and the compressive strength is currently being studied.

Tensile strength of PICA-15 in both transverse and in-plane directions was measured by using the Instron 1211. The transverse direction is defined as the casting direction, which is perpendicular to the ablating surface, and the in-plane direction is parallel to the ablating surface. Fifteen one-inch cube samples were measured for each direction to give the average values, standard deviations, and the coefficient of variation listed in table 2. Coefficient of variation is defined as the ratio of standard deviation to the mean value. Figures 12 and 13 show the typical stress-strain curves of PICA-14 in both transverse and in-plane directions, respectively. As expected, PICA is quite brittle, and the failure strain is less than 1.0%, and the failure strain in the transverse direction is a factor of two higher than that of the in-plane direction. The tensile strength of the transverse direction is about one order of magnitude lower than that of the in-plane direction. This behavior is very typical in fibrous materials.

## 3. High Enthalpy, Hypersonic Flow Environment

### *a. Facility*

An arc-jet test series was conducted in the Ames 60 megawatt (MW) Interaction Heating Facility (IHF). In general, an arc-jet facility uses an electrical discharge to heat a gas stream to a very high temperature. The test gas, which is air for the case of the IHF facility, is heated by an electrical discharge within a 3.15 inch diameter constrictor column (ref. 4). The heated gas is then supersonically expanded through a converging-diverging, 13 inch diameter conical nozzle exit, and discharged into an evacuated test chamber where the test model is

mounted onto a swing arm. The resulting highly energetic, or high enthalpy, flow can simulate the aerothermodynamic heating environments experienced by space vehicles during planetary entry or earth re-entry. The IHF can produce enthalpies approaching 20,000 Btu/lbm and velocities up to Mach 8.

Calibration tests were first performed to determine the heat fluxes and stagnation pressures at given facility conditions. Heat fluxes and stagnation pressures were varied by adjusting the facility current, air pressure, and test model distance from the nozzle exit. A four-inch flat faced copper calibration probe, shown in figure 14, was instrumented with two slug calorimeters to measure the heat fluxes, and a pressure port to measure the stagnation pressures. For test conditions that required high stagnation pressures at lower heat fluxes, cold air was injected downstream of the arc heater. This “add air” condition increases the total chamber pressure, and in turn, increases the stagnation pressure on the test model. Several calibration runs were conducted at each test condition to verify repeatability and to obtain statistical data. Since heat flux is dependent on the model nose radius, the data obtained from the calibration probe was related to each model size through a simplified Fay-Riddell equation (ref. 5):

$$\dot{q}_{\text{hemi}} = C \sqrt{P_{t2} / R_n} \quad (1)$$

where  $\dot{q}_{\text{hemi}}$  is the heat flux in Btu/ft<sup>2</sup>-s on a hemispherical surface,  $P_{t2}$  is the stagnation pressure,  $R_n$  is the nose radius of the test model, and  $C$  is the total heat transfer coefficient. Stewart’s correlation (ref. 6) is then used to relate the hemispherical surface to the flat faced cylinder of the same base radius:

$$\dot{q}_{\text{FF}} = 1.87 \dot{q}_{\text{hemi}} \quad R_n = R_b \quad (2)$$

Table 3 shows the calibration data from the calibration probe and the resulting heat fluxes for each test model size. The facility current, arc chamber air pressure ( $P_{ch}$ ), total pressure ( $P_t$ , includes  $P_{ch}$  and “add air” pressure), and calorimeter position ( $x$ ) are listed in the facility conditions section of table 3. The stagnation pressure and cold wall heat flux,  $\dot{q}_{\text{cal}}$ , are the measurements taken from the calibration probe. The remaining columns are the resulting heat fluxes on the various model sizes. The correlation of equation 2 is only valid if the  $R_c/R_b$  ratio is less than 0.31, where  $R_c$  is the corner edge radius and  $R_b$  is the base radius of the model (ref. 7).

The stagnation point, cold wall heat flux on models with diameters less than 4.0 inches was corrected for the effect of corner radius, as shown in the last three columns of table 3. Zoby and Sullivan (ref. 7) developed a scheme to determine the effect of corner radius on stagnation-point

velocity gradients on blunt bodies at 0° angle of attack. The blunt bodies used in their studies consisted of a range of ratios of body radius to nose radius,  $R_b/R_n$ , from 0.0 (flat-faced cylinder) to 1.0 (sphere), and ratios of corner radius to body radius from 0.0 (sharp) to 0.3. The results from Zoby’s studies were used to calculate the effective radius for each model size since the heat flux is proportional to the square root of the velocity gradient.

#### b. Test Models

Test models of various shapes and sizes, as shown in figure 15, were produced to allow testing in a wide range of cold wall heat fluxes. Still photographs, video during tests, weight, and thickness measurements were taken at pre- and post-test for each model. The thickness measurement used a height gage and a template, shown in figure 16, to ensure that the measurements were taken at the same points on the model surface before and after testing. The thickness of the cylindrical-shaped test models was measured with a caliper due to its geometry. Most models were instrumented with one to three K-type thermocouples to measure the in-depth temperature response of the material during test and during the cool-down period. Surface temperatures were measured by two 2-color optical pyrometers; one was mounted inside the test chamber, and the other was outside the test chamber. The pyrometer outside of the test chamber viewed the test model’s surface by way of a gold mirror, through a quartz viewing window; therefore, the temperature obtained from the outside pyrometer requires a correction for window transmission losses.

#### 4. Material Thermal Response Modeling

The material thermal response model was generated using the Charring Materials Analysis code (CMA) from Aerotherm Corp. The thermal model was validated with thermocouple data from the arc jet testing. The results of the analysis consist of the B-prime table, effective thermal conductivity, effective specific heat, and decomposition kinetics of PICA. The CMA analysis uses the reaction rate information obtained from the TGA curves and XPS of the char to generate the input deck and B-prime curves. The measured thermal conductivity and thermocouple data from the arc jet testing are used in the fine adjustment and validation of the thermal model. A set of effective thermal properties and B-prime curves are generated once the model is validated.

#### 5. X-ray Photoelectron Spectroscopy (XPS)

Elemental composition analysis of virgin PICA and a charred sample was performed using X-ray Photoelectron Spectroscopy (XPS). XPS measures the kinetic energy of

photoelectrons produced from a single x-ray source. The kinetic energy,  $E_{KE}$ , is then used to calculate the binding energy,  $E_{BE}$ , using the following equation:

$$E_{BE} = h\nu - E_{KE} - \Phi \quad (3)$$

XPS survey yields elemental compositions and bonding information to enable determination of composition and compound characteristics of materials.

## 6. Infrared (IR) and Ultraviolet (UV) Spectrophotometry<sup>3</sup>

The spectral hemispherical reflectance of virgin and charred PICA specimens was measured at room temperature over a wavelength range of 0.25  $\mu\text{m}$  to 18  $\mu\text{m}$ . A Perkin-Elmer Lambda-9 spectrophotometer was used for measurements from 0.25  $\mu\text{m}$  to 2.5  $\mu\text{m}$  and a BIORAD FTS-40 spectrophotometer was used for measurements from 2.5  $\mu\text{m}$  to 18.0  $\mu\text{m}$ .

## Results and Discussion

### 1. Arc-Jet Test Results

Test conditions are tabulated in table 4 and test results, shown in table 5, are arranged in order of increasing heat flux and stagnation pressure. The density of each test sample is listed, as well as pre- and post-test measurements of weight and sample thickness. The resulting mass loss and stagnation point recession were then calculated and are also listed in table 5. Average recession values are the average of all recession points obtained from the template. The recession on the outer edge of the model surface is higher than that of the stagnation region due to higher heating and shear stress on the corner edge of the flat faced cylinder. Surface temperatures, measured by the optical pyrometers, are also reported in table 5. The effective heat of ablation,  $H_{eff}$ , is included in the table to evaluate the performance of each material and is normalized to the virgin density. The effective heat of ablation is defined as follows (ref. 1):

$$H_{eff} = \frac{\dot{q}_{cw}}{\dot{s}\rho_v} \quad (4)$$

where  $\dot{q}_{cw}$  is the stagnation point cold wall heat flux,  $\dot{s}$  is the recession rate (average recession divided by test time), and  $\rho_v$  is the density of the virgin PICA sample.

#### a. Standard PICA samples

Test results of standard PICA samples can be divided into three different regimes. In the first regime, at a cold wall heat flux range of 300 to 400 Btu/ $\text{ft}^2\text{-s}$ , as shown in table 5, the ablation performance is oxidation rate controlled. The recession, caused primarily by oxidation, is evident by the decreasing trend of the effective heat of ablation as the stagnation pressure increases. In this heating range, the higher the stagnation pressure, the higher the concentration of oxygen atoms diffusing into the boundary layer, therefore the higher oxidation rate and thus a higher surface recession.

At heating rates above 400 Btu/ $\text{ft}^2\text{-s}$ , up to 1400 Btu/ $\text{ft}^2\text{-s}$ , the ablation characteristic of PICA is diffusion controlled, and the main mechanism of heat rejection is re-radiation. The material becomes more efficient with increasing stagnation pressure, and is evident by the increasing trend in  $H_{eff}$ . Figure 17 shows the effective heat of ablation as a function of cold wall heat flux for standard PICA at stagnation pressures from 0.11 to 0.43 atm. The  $H_{eff}$  curve shows that PICA is most efficient at a heating rate range of 1200 to 1800 Btu/ $\text{ft}^2\text{-s}$  at 0.43 atm. Due to arc jet facility limitations, it was not possible to test PICA material at stagnation pressures above 0.43 atm. Major modification to the facility is required to accomplish such testing.

The third regime, sublimation rate controlled, occurs at heating rates above 1800 Btu/ $\text{ft}^2\text{-s}$  where the surface recession is primarily due to sublimation of the carbon. The surface temperature at this heating range is extremely high, such that the carbon fibers at the surface begin to sublime, thus contributing to the high recession. It is interesting to note that  $H_{eff}$  at these heating rates is still significantly higher than that of the oxidation regime.

Visual inspection of models at post test shows no sign of spallation, i.e., the recessed surface is very smooth, including the corner edge where the heating rate and shear stress is almost double that of the stagnation region (ref. 8). Appendix E shows two examples of the pre- and post-test condition the PICA models.

Figure 18 shows the in-depth temperature response for a standard PICA sample at 500 Btu/ $\text{ft}^2\text{-s}$ , 0.42 atm stagnation pressure, and a total heat load of 12,500 Btu/ $\text{ft}^2$ . Surface temperature, measured by the optical pyrometer and corrected for actual material emissivity and transmission losses due to the viewing window and mirror, is plotted on the primary y-axis. In-depth temperatures, measured by thermocouples, are plotted on the secondary y-axis. Thermocouple locations were measured more precisely after testing, and actual locations are labeled on the plots. While the surface temperature is approaching

<sup>3</sup>Estimation of temperature dependent emittances for PICA. Analysis and measurements were done by Jochen Marschall of Thermosciences Institute at Ames Research Center.

5000°F, approximately 0.5 inch from the surface the temperature peaks at about 1800°F. Even more dramatic is that at 1.2 inches from the surface, the temperature peaks at only 700°F, and at 1.6 inches from the surface, the temperature reaches only 300°F after 270 seconds. These results demonstrate the fairly good insulative properties of PICA, and indicate that most of the heat is rejected by reradiation. Figure 18 also shows that PICA has a very low heat capacity and since the material has 85% porosity, the heat is being rejected at the surface rather than stored in heat conduction. This thermal response result shows that PICA could be directly bonded to the structure of a vehicle without additional insulation, and complex heat shield ejection is not required for planetary entry missions. In most cases, the ablative heat shield is directly bonded to the spacecraft structure; however, additional thickness of the heat shield is used to maintain the desirable structure temperature. PICA thickness could be minimized due to its good in-depth thermal response. As shown in table 4, the same instrumentation scheme was used for other models at other test conditions, and the in-depth temperature responses for these models are included in Appendix A.

#### *b. Surface densified PICA samples*

Surface densification was performed on several PICA samples in an attempt to improve the ablation characteristics of PICA at high stagnation pressure test conditions without significantly increasing the overall density of PICA. The first four surface densified PICA samples were produced with different densification methods (shown in table 1) to determine the best composition. These four samples were tested at 575 Btu/ft<sup>2</sup>-s for 25 seconds, and the result, shown in table 5, shows a variation in both surface recession and  $H_{eff}$ . A similar trend of ablation characteristics is observed for the surface densified PICA where the material is most efficient at heating rates above 1200 Btu/ft<sup>2</sup>-s. Figure 19 shows that  $H_{eff}$  peaks at about 1200-2100 Btu/ft<sup>2</sup>-s, and has not yet shown any signs of failure due to spallation.

A comparison of in-depth temperature responses is shown in figure 20 for standard and surface densified PICA samples at 750 Btu/ft<sup>2</sup>-s, 0.43 atm stagnation pressure, and a total heat load of 18,750 Btu/ft<sup>2</sup>. The surface temperature of the densified sample is approximately 4800°F, slightly less than standard PICA, and at 1 inch from the surface, the densified sample in-depth temperature peaks around 540°F, 125 degrees less than the standard PICA. At 1.5 inches from the surface, the densified sample temperature reached 335°F, approximately 15 degrees less than the standard PICA sample. These temperature profiles of standard PICA and surface densified PICA show a small difference in the in-depth

temperature response between the two materials. It is perhaps due to a relatively thin layer of densification (0.25 inch depth) which absorbs more energy to pyrolyze the additional phenolic and thus allows less energy to penetrate into the model. In addition, the charred surface is being densified by the pyrolysis of the phenolic and thus reduces hot gas ingestion, or in-flow, which would influence the in-depth thermal response. More thermal response and ablation data for surface densified PICA will be obtained in future arc jet tests.

Additional in-depth thermal responses of other surface densified PICA samples, tested at a wide range of heat fluxes, are included in Appendix B. Visual inspection of the surface of the post-test models indicates that the surface densified PICA has a smoother surface than that of standard PICA. This observation is expected since the densified PICA has a higher loading of phenolic, which deposits a high char residue at the surface.

#### *c. Carbon Fiberform samples*

Several samples of the carbon substrate were tested to compare against the PICA samples at similar conditions. Figure 21 shows the performance of the carbon samples as a function of cold wall heat flux at various stagnation pressures. The  $H_{eff}$  drastically decreases at heating rates above 1200 Btu/ft<sup>2</sup>-s where the carbon Fiberform exhibits mechanical failure. The carbon samples burned through at 750 Btu/ft<sup>2</sup>-s and 0.34 atm stagnation pressure, and at 1200 Btu/ft<sup>2</sup>-s and 0.34 atm stagnation pressure. The Fiberform does not have sufficient strength to withstand the high stagnation pressures, and thus recessed considerably at low heating and stagnation pressure conditions.

The carbon Fiberform test samples were instrumented with one thermocouple, and figure 22 shows an example of the carbon Fiberform tested at 1225 Btu/ft<sup>2</sup>-s, 0.23 atm stagnation pressure, and a total heat load of 24,500 Btu/ft<sup>2</sup>. At 1.5 inches from the surface, the temperature peaks at about 600°F. The low surface temperature measurement was due to the misalignment of the pyrometer. This in-depth thermal response demonstrates the effect of internal radiative heat transfer, mentioned above, on the thermal conductivity of carbon Fiberform. As expected, the ablating surface of the undamaged Fiberform samples was significantly rougher than that of the PICA.

#### *d. Avcoat-5026 sample*

Because of the limited supply of Avcoat and the fact that it is no longer commercially manufactured, only one sample of the material was tested to compare with PICA. Avcoat is the ablative material used as the forebody heat shield on the Apollo. The Avcoat sample was tested at a

very high heating condition; a cold wall heat flux of 2960 Btu/ft<sup>2</sup>-s, a stagnation pressure of 0.43 atm, and a total heat load of 29,600 Btu/ft<sup>2</sup>. Avcoat material was previously tested at lower heating rates (ref. 1), and a PICA sample was also tested at one of these conditions for comparison purposes. The Avcoat sample had a higher recession rate than the PICA material and thus its effective heat of ablation was approximately 32% of the PICA material.

To achieve the very high heating condition, the geometry of the model was limited to a 0.500 inch radius cylinder with a hemispherical nose. This geometry limits the instrumentation schemes, and thus, the thermocouple locations of the Avcoat model were not identical to that of the PICA models. The surface temperature of the Avcoat sample, as shown in figure 23, is approximately 800°F less than the surface temperature of the PICA sample tested at the same condition, due to the high blowing rate and high thermal conductivity of the Avcoat material.

## 2. Computational Material Response Using CMA

A material thermal response model for PICA was generated from CMA93. CMA is typically used to model one-dimensional transient transport of thermal energy in a three-dimensional isotropic material which can ablate at the surface, and can decompose in-depth. The material's preliminary physical, thermal, and optical property measurements are used to generate an input deck (included in Appendix C), and arc jet testing data is used to validate the thermal model. The thermal response model includes the B-prime table, effective thermal conductivity, effective specific heat, and decomposition kinetics. The validated thermal response model is then used in calculating the required thickness of the heat shield. Figures 24(a) and (b) are the resulting effective thermal conductivity and effective specific heat of virgin PICA and the char. As shown in figure 24(a), the thermal conductivity of virgin PICA is initially lower than that of the charred PICA, and the trend crosses over at 3100°F. This thermal response is expected since the char consists of highly conductive graphite material (see XPS analysis section below) whereas the loading of the phenolic resin in the virgin PICA reduces the pore size and thus reduces the internal radiation effect. Above 3100°F, the phenolic within the PICA layer pyrolyzes and becomes charred. However, in most analyses, the thermal conductivity of PICA is only valid at temperatures below 2000°F. Figure 24(a) also shows that the measured thermal conductivity is lower than that obtained from CMA. Figure 25 shows the B prime curves for char and gas pyrolysis at several pressures. As expected, the B prime curves shift to the right as the pressure decreases.

## 3. Thermogravimetric Analysis (TGA)

As an aid to understanding the thermal response and ablation characteristics of PICA, a few post-test PICA models were sectioned for further analysis. Figure 26 illustrates different regions in a cross-sectioned post-test PICA sample (PICA-M2-7) tested at 1065 Btu/ft<sup>2</sup>-s, 0.34 atm stagnation pressure, and a total heat load of 26,625 Btu/ft<sup>2</sup>. Material was removed at five stations and analyzed with TGA. Resin content, Re(%), for each station was calculated based on the total mass loss from the TGA results and is defined as follows:

$$Re(\%) = \frac{m_r}{m_p} \times 100 \quad (5)$$

where  $m_r$  is the mass loss of the sample, or mass removal, and  $m_p$  is the mass loss of pyrolyzed phenolic resin. The resin content at each of the five locations is shown in figure 27. The char interface is very thin compared to that of the pyrolysis interface. A sample from the pyrolysis region, approximately 0.4 inch from the surface, has a 6.1% resin content, and the pyrolysis/virgin sample, at approximately 0.75 inch from the surface, has a 23.7% resin content. The resin content reported for the station #5 was measured at 38.8%, which is consistent with the TGA results shown in figure 11(a). Thickness of the char and pyrolysis zones are estimated to be 0.12 inch and 0.6 inch, respectively. The thick pyrolysis zone is perhaps due to PICA's high porosity which allows pyrolysis gas to percolate to the front surface. Gas percolation is one of the primary advantages in heat rejection for ablative heat shield materials.

## 4. X-ray Photoelectron Spectroscopy (XPS)

X-ray Photoelectron Spectroscopy (XPS) analysis was conducted by Charles Evans & Associates to obtain the elemental composition of small samples from PICA-M2-7, which was tested at 1065 Btu/ft<sup>2</sup>-s, 0.34 atm stagnation pressure, and a total heat load of 26,625 Btu/ft<sup>2</sup>. The XPS analysis was performed on the char and the virgin portions of the sample. As shown in table 6, the char was almost entirely carbon, and the virgin sample was predominantly carbon, with some oxygen, nitrogen, and silicone. The presence of silicone was due to contamination from the machining of the samples for analysis.

## 5. Infrared (IR) and Ultraviolet (UV) Spectroscopy

Infrared (IR) and Ultraviolet (UV) reflectant spectra were obtained for some of the post-test samples and IR results are included in the Appendix D. A Perkin-Elmer Lambda-9 spectrophotometer was used for measurements

from 0.25  $\mu\text{m}$  to 18  $\mu\text{m}$  and a BIORAD FTS-40 spectrophotometer was used for measurements from 2.5  $\mu\text{m}$  to 18.0  $\mu\text{m}$ . Measured reflectances were converted to emittances using the expression

$$\epsilon(\lambda, T_R) = 1 - \rho(\lambda, T_R) \quad (6)$$

which is valid for a diffusely irradiated opaque surface in thermal equilibrium with its surroundings at a temperature  $T_R$ . The temperature dependence of the wavelength integrated hemispherical emittance is estimated by averaging the room temperature spectral emittance values over the Planck distribution function at temperature  $T$ , i.e.,

$$\epsilon(T) = \frac{\int_{\lambda_l}^{\lambda_u} \epsilon(\lambda, T_R) e_{\lambda b}(\lambda, T) d\lambda}{\int_{\lambda_l}^{\lambda_u} e_{\lambda b}(\lambda, T) d\lambda} \quad (7)$$

Here  $\lambda_l$  and  $\lambda_u$  are, respectively, the lower and upper limits of the wavelength range over which  $\rho(\lambda, T_R)$  was measured and  $e_{\lambda b}(\lambda, T)$  is the Planck distribution. This estimation procedure assumes that the spectral hemispherical reflectance is a weak function of temperature and that the dominant contribution to the temperature dependence of hemispherical emittance arises from the wavelength weighting of the Planck function. Planck's distribution was used to calculate the emissivity as a function of temperature and is shown in figure 28. The emittance of the virgin PICA is 0.805 at room temperature and increases to 0.9 at 3000°F, at which PICA is charred. The emittance of the char is 0.91 and decreases with temperatures to 0.89.

## Conclusion

An extensive arc-jet test series was conducted to further investigate the newly developed PICA material. The thermal performance and ablation characteristics were observed from testing in a wide range of cold wall heat fluxes, stagnation pressures, and total heat loads. Several material characterization tests were also performed to investigate various properties of the virgin and charred PICA material.

Figure 29 summarizes the thermal performance of PICA, surface densified PICA, Fiberform, and Avcoat materials as a function of cold wall heat fluxes. The effective heat of ablation of surface densified PICA is about factor of two higher than that of PICA and is an order of magnitude higher than that of Avcoat material. The

Fiberform performed poorly; especially where the stagnation pressure exceeded 0.3 atm regardless of the heating rates. The ablation characteristic of PICA is very uniform, and no spallation occurred at pressures as high as 0.43 atm. In-depth temperature profiles reveal fairly good insulative properties and show that PICA heatshield thickness could be minimized due to its good in-depth thermal response.

Surface densification of PICA showed promising improvement over standard PICA, in terms of surface recession. Testing of surface densified PICA shows lower surface temperatures, less recession, and thus higher effective heats of ablation. In-depth thermal response of densified PICA showed a small difference when compared to standard PICA, which is consistent with the fact that the surface densification only affects the surface properties and performance. This improvement could be significant for future far-planet discovery missions where surface pressures could reach as high as 10 atm and heating rates above 1500 Btu/ft<sup>2</sup>-s. Surface densified PICA and standard PICA offer great weight savings over conventional ablatives, i.e., Avcoat and carbon-phenolic, due to their low density, low thermal conductivity, and high effective heat of ablation. These new materials offer a weight savings of more than 50% over the traditional ablatives, and that savings could be directly translated to an increase in scientific payload.

				2.1

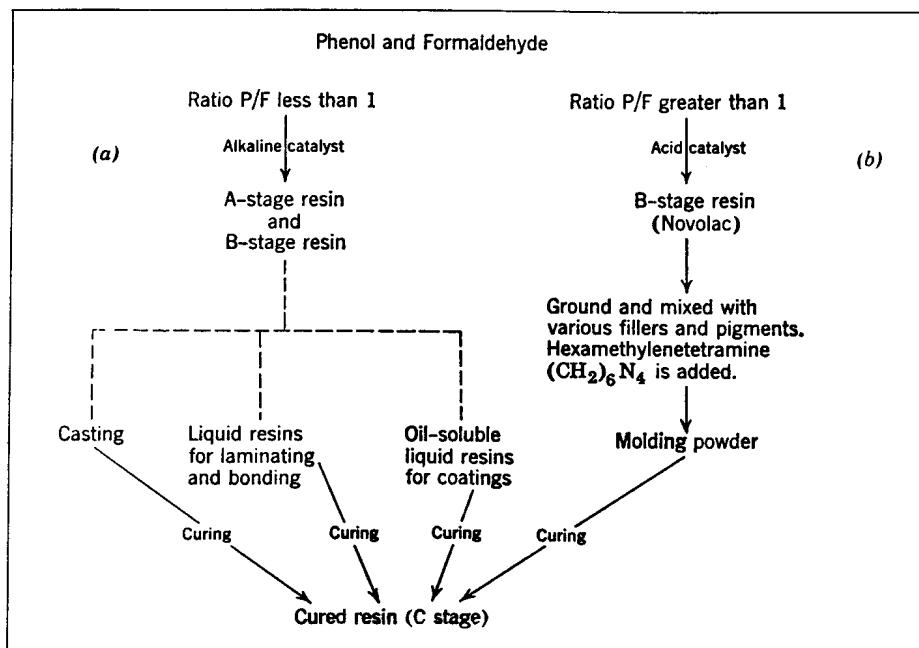

Figure 1. Production of phenol-formaldehyde resins. (a) One-stage process; the reaction is interrupted at A- or B-stage resins to prevent crosslinking. (b) Two-stage process; because of deficiency of formaldehyde ( $P/F > 1$ ), the reaction can be carried out nearly to completion without three-dimensional crosslinking. Final crosslinking is accomplished after application of A- or B-stage resins or molding powder to produce a thermoset material.

13. ABSTRACT ( <i>Maximum 200 words</i> )  This paper presents the development of the light weight Phenolic Impregnated Carbon Ablators (PICA) and its thermal performance in a simulated heating environment for planetary entry vehicles. The PICA material was developed as a member of the Light Weight Ceramic Ablators (LCAs), and the manufacturing process of this material has since been significantly improved. The density of PICA material ranges from 14 to 20 lbm/ft <sup>3</sup> , having uniform resin distribution with and without a densified top surface. The thermal performance of PICA was evaluated in the Ames arc-jet facility at cold wall heat fluxes from 375 to 2,960 Btu/ft <sup>2</sup> -s and surface pressures of 0.1 to 0.43 atm. Heat loads used in these tests varied from 5,500 to 29,600 Btu/ft <sup>2</sup> and are representative of the entry conditions of the proposed Discovery Class Missions. Surface and in-depth temperatures were measured using optical pyrometers and thermocouples. Surface recession was also measured by using a template and a height gage. The ablation characteristics and efficiency of PICA are quantified by using the effective heat of ablation, and the thermal penetration response is evaluated from the thermal soak data. In addition, a comparison of thermal performance of standard and surface densified PICA is also discussed.
